Estimation of an Education Production Function under Random Assignment with Selection

By Eleanor Jawon Choi and Hyung Sik Roger Moon and Geert Ridder *

This paper estimates an education production function using data on the College Scholastic Ability Test (CSAT) score and high school characteristics from Seoul, Korea. A unique institutional feature of the high school system in Seoul is that on entering high school students are randomly assigned to schools within each school district. The main contribution of our study is to derive a school production function by aggregating the individuals’ potential outcome functions that depend on observed and unobserved school inputs interacted with heterogeneous and unobserved individual abilities. The school production function derived under random assignment and under the assumption that there are no cohort effects has three unique features that have not been considered in previous studies. First, its average (over students) coefficients on school inputs do not differ by school or over time, but by district. This is a consequence of the endogenous sorting of students between districts combined with the random assignment to schools within districts. Second, it allows unobserved school effects to be potentially correlated with observed ones. Third, the weighted average of the district-specific school input effects with weights equal to the fraction of the population in the districts is equal to the average partial effect (APE) of school inputs on individual academic achievement. To estimate the school production function coefficients, we first obtain district-specific coefficients using the fixed effect estimation method in school level panel data for each district and compute the weighted average described above. The empirical findings are (i) the school production function coefficients do differ between districts, which may be due to potentially endogenous sorting of students or unobserved differences in district characteristics, (ii) our estimate of the single-sex school effect is much larger than that found in previous studies most of which assumed constant school input coefficients across districts and did not consider school fixed effects.

I. Background and Data

The education policy in Korea over the past four decades greatly emphasized equal educational opportunity. In accordance with the policy emphasis, the High School Equalization Policy (HSEP) was adopted in Seoul in 1974. The HSEP aimed to provide students with a uniform learning environment and to close the achievement gap across schools by minimizing across-school variation in student quality, teacher quality, and school facilities and curriculum. Under the HSEP, students were randomly assigned to academic high schools within school districts where they met residency requirements. The

We thank Jaesung Choi, Cheolsung Park, Jinyoung Kim, Seik Kim, David Lee, Nayoung Lee and Hongliang Zhang for helpful conversations; Korea Education and Research Information Service (KERIS) and the Ministry of Education of the Republic of Korea for providing data; and Yoonju Jung for research assistance. Choi gratefully acknowledges funding from Hanyang University (HY-20130000000418). Moon appreciates financial support from the USC Lusk Center for Real Estate.

Meghir and Rivkin [2011] provides an overview of the literature on education production. See references therein. Park, Behrman and Choi [2012] uses the same data as in this study to investigate the effect of single sex education on student achievement.

For more information on school choice and residential sorting, see, for example, Bayer, Ferreira and McMillan [2007].

3 The strong emphasis on equal treatment in education policy has been maintained until 2009. The policy focus has shifted from uniformity to diversity afterward. Policymakers started to encourage competition among schools in 2010.

4 For more information on the HSEP and its impacts, see, for example, Kim, Lee and Lee [2008].

5 The student assignment lottery covered academic high schools in ten school districts, including Districts 1-4, 6-11. High schools excluded from the random assignment were vocational

lottery-based student assignment. For the 2008 and 2009 cohorts of seniors, the assignment was conducted in February 2006 and 2007, respectively.\textsuperscript{10} The analysis sample covers about 60 percent of CSAT takers in Seoul — 50,809 students in 2008 and 58,905 in 2009. Table 1 shows means and standard deviations of school level variables that are included in our empirical specifications. We focus on boys here and numbers for girls are shown in the online appendix.

II. Econometric Framework

A. The Individual Potential Outcome

We consider the following potential outcome of individual $i$ in $I$ at school $s$ ($d$) in $S_d$ of district $d$ in $D$ in year $t$ in $T$. We assume a linear education production function with heterogeneous coefficients:

\begin{equation}
Y_i (s, d, t) = K_{s(d)}' \alpha_i + L_{s(d), t} \beta_i + v_{s(d), t} \omega_i + u_{s(d), t} \xi_i + c_d \eta_i.
\end{equation}

The (potential) outcome $Y_i (s, d, t)$ is the (potential) CSAT score of student $i$ if he attends school $s$ ($d$) of district $d$ in year $t$. The variables $K_{s(d)}$ and $L_{s(d), t}$ denote time-invariant and time-varying school inputs, respectively. The variables $v_{s(d), t}$ and $u_{s(d), t}$ respectively, represent the unobserved time-invariant school inputs and unobserved time-varying school inputs. The variable $c_d$ represents (unobserved) district characteristics. The coefficients $\{\alpha_i, \beta_i, \omega_i, \xi_i, \eta_i\}$ represent heterogeneous individual responses to the school inputs (observed and unobserved) and the unobserved district characteristics. The specification of the potential outcome model for $Y_i (s, d, t)$ assumes that the potential outcome is determined by the interaction of the school level inputs and the district characteristics $\{K_{s(d)}, L_{s(d), t}, v_{s(d), t}, u_{s(d), t}, c_d\}$ (observed and unobserved) and the individual (heterogeneous) coefficients $\{\alpha_i, \beta_i, \omega_i, \xi_i, \eta_i\}$\textsuperscript{11}.

Suppose that $S_i$ denotes the school that individual $i$ attends, $T_i$ denotes the senior year of individual $i$, and $D_i$ is the district where individual $i$ chose to live. The observed outcome, i.e. the CSAT score, of individual $i$ is

\begin{equation}
Y_i = Y_i (S_i, D_i, T_i).
\end{equation}

Note that the outcomes $(Y_i, S_i, D_i, T_i)$ are observed at the individual level, and $(K_{s(d)}, L_{s(d), t})$ at the school level.

The parameters of interest are the APE of the school inputs of interest $K_{s(d)}$ and $L_{s(d), t}$\textsuperscript{12}:

\begin{equation}
\alpha = \mathbb{E} [\alpha_i] \text{ and } \beta = \mathbb{E} [\beta_i].
\end{equation}

B. School Production Function

The school production function is the aggregate of the individual outcome functions and depends on the school level inputs. The aggregation is done under the following two key assumptions.

ASSUMPTION 1: We assume that for all $(s, d, t)$,

\begin{equation}
\mathbb{E} \left[ (\alpha_i, \beta_i, \omega_i, \xi_i, \eta_i) \mid S_i = s, D_i = d, T_i = t \right] = \mathbb{E} \left[ (\alpha_i, \beta_i, \omega_i, \xi_i, \eta_i) \mid D_i = d, T_i = t \right].
\end{equation}

ASSUMPTION 2: We assume that for all $t$,

\begin{equation}
\mathbb{E} \left[ (\alpha_i, \beta_i, \omega_i, \xi_i, \eta_i) \mid D_i = d, T_i = t \right] = \mathbb{E} \left[ (\alpha_i, \beta_i, \omega_i, \xi_i, \eta_i) \mid D_i = d \right].
\end{equation}

Assumption\textsuperscript{11} follows from the random assignment of students within school districts. Assumption\textsuperscript{12} assumes that the district average of student abilities does not change over time. This assumption is justified if the distribution of student abilities and the district choice selection does not change across cohorts. Given that our data covers two consecutive years, Assumption\textsuperscript{12} is reasonable.

The average input effects for students in district $d$ are denoted by

\begin{equation}
(\alpha_d, \beta_d, \omega_d, \xi_d, \eta_d) = \mathbb{E} \left[ (\alpha_i, \beta_i, \omega_i, \xi_i, \eta_i) \mid D_i = d \right].
\end{equation}

If the individual district choice is independent of the individual input effect, then $\alpha = \alpha_d$ and $\beta = \beta_d$. In the case we study, however, the average productivity of school inputs may differ by school district because students were likely to be sorted endogenously across districts. By

\textsuperscript{10}The school year begins in early March and ends in mid February in Korea.

\textsuperscript{11}In the potential outcome function [1], we do not include a time effect because the CSAT scores are normalized.

\textsuperscript{12}\mathbb{E} \{\cdot\}$ denotes the population average of individuals.
allowing the average productivity to differ between districts, we explicitly take into account the potentially endogenous district selection.

We define $Y_{s(d),d,t}$ as the average test score of school $s$ in district $d$ in year $t$. Under Assumptions 1 and 2, the average test score of school $s$ can be expressed as

$$Y_{s(d),d,t} = \frac{\sum_{t \in T} Y_{s(t) \mid S_t = s, D_t = d, T_t = t}}{\sum_{t \in T} \mathbb{I} \{S_t = s, D_t = d, T_t = t\}} = K'_{s(d),t} \alpha_d + L'_{s(d),t,\beta_d} + u(s(d),t) \xi_d + c_d \eta_d.$$

For notational convenience, we will also use the simplified subscripts $Y_{s,d,t} = Y_{s(d),d,t}$, $K_{s,d} = K_{s(d)}$, $L_{s,d,t} = L_{s(d),t}$, $V_{s,d} = v(s,d) \xi_d$, $U_{s,d,t} = u(s(d),t) \xi_d$, and $C_d = c_d \eta_d$. Then, we can write the average outcome of school $s$ in district $d$ and year $t$ as a function of school inputs and district characteristics:

$$Y_{s,d,t} = K'_{s,d} \alpha_d + L'_{s,d,\beta_d} + v_{s,d} + U_{s,d,t} + C_d,$$

which yields the school production function.

Note that we derive the school production function by aggregating the individual outcomes. This procedure is similar to the derivation of the market demand function as an aggregation over individual choices (Berry, Levinsohn and Pakes (1995)). The school production function (2) has the unique feature that the coefficients $\alpha_d$ and $\beta_d$ of the observed school inputs are district specific, but constant across schools within each district and over time. The random assignment of students within districts and the assumption of no cohort effects are key for the constant productivity of school inputs within a district. Notice that if there is no individual heterogeneity in the potential outcome, which is a very strong restriction, it follows that $\alpha_d = \hat{\alpha}$ and $\beta_d = \hat{\beta}$. Under self-selection of schools and individual heterogeneity, the school production function is a correlated random coefficient model, and the identification of the school input coefficients ($\alpha_{s(d)}, \beta_{s(d)}$) using school level data becomes challenging. In our setup, district specific coefficients ($\alpha_d, \beta_d$) are district averages of $(\alpha_t, \beta_t)$.

## C. Estimation of $\alpha$ and $\beta$

For identification, we assume that

$$\mathbb{E} \left[ U_{s,d,t} \mid \left\{ L_{s,d,t} : t \in T \right\} \right] = 0,$$

$$\mathbb{E} \left[ \sum_{t \in T} U_{s,d,t} / T \mid K_{s,d} \right] = 0,$$

and

$$\mathbb{E} \left[ V_{s,d} \mid K_{s,d} \right] = \mathbb{E} \left[ V_{s,d} \right].$$

The usual identification assumptions imply strict exogeneity of $L_{s,d,t}$ with respect to time-varying unobserved school effects, $U_{s,d,t}$, and exogeneity of $K_{s,d}$ with respect not only to the time average of $U_{s,d,t}$ but also to $V_{s,d}$.

The APE parameters of interests are

$$\hat{\alpha} = \mathbb{E} \left[ \mathbb{E} \left[ \alpha_t \mid D_t = d \right] \right] = \sum_{d \in D} \alpha_d \mathbb{P} \left( D_t = d \right),$$

$$\hat{\beta} = \mathbb{E} \left[ \mathbb{E} \left[ \beta_t \mid D_t = d \right] \right] = \sum_{d \in D} \beta_d \mathbb{P} \left( D_t = d \right).$$

We can estimate $\alpha$ and $\beta$ by taking the averages of estimated $\alpha_d$ and $\beta_d$ weighted by the district choice probabilities:

$$\hat{\alpha} = \sum_{d \in D} \hat{\alpha}_d \frac{N_d}{N} \quad \text{and} \quad \hat{\beta} = \sum_{d \in D} \hat{\beta}_d \frac{N_d}{N},$$

where $N_d$ is the number of students in district $d$ and $N$ is the total number of students in Seoul.

In view that the school production function (2) takes a panel linear regression form within

</table>

Note: *, **, and *** indicate significance at 10 percent, 5 percent, and 1 percent level, respectively. Robust standard errors in parentheses. Standard errors clustered in school level for coefficients on time-varying regressors. See the text for the list of time-varying and time-invariant control variables.
each district, we can obtain a within estimator of $\beta_d$ using fixed effect estimation district by district.

$$
\hat{\beta}_d = \left[ \sum_{s \in S_d} \sum_{t \in T} [\mathbf{L}_{s,d,t} - \mathbf{\Gamma}_{s,d,*}] [\mathbf{L}_{s,d,t} - \mathbf{\Gamma}_{s,d,*}]' \right]^{-1} \times \sum_{s \in S_d} \sum_{t \in T} [\mathbf{L}_{s,d,t} - \mathbf{\Gamma}_{s,d,*}] [Y_{s,d,t} - \bar{Y}_{s,d,*}].
$$

Then, $\alpha_d$ can be estimated as follows:

$$
\hat{\alpha}_d = \left[ \sum_{s \in S_d} [K_{s,d} - K_{s,*}] [K_{s,d} - K_{s,*}]' \right]^{-1} \times \sum_{s \in S_d} [K_{s,d} - K_{s,*}] [1/T \sum_{t \in T} Y_{s,d,t} - \mathbf{L}_{s,d,*}' \hat{\beta}_d].
$$

### III. Results and Discussion

Table 2 presents the estimated school input effects, especially the effect of single-sex education and the senior class size for boys. Regressions also include other time-varying and time-invariant covariates that serve as control variables and are possibly correlated with unobserved school characteristics. Time-varying controls include the fraction of students receiving free or reduced price lunch, annual development fund spending per student, and the fraction of female teachers. Time-invariant controls include a private school indicator, age of the school in 2008, and the interaction between the two.

From columns (1)-(6), we observe that single-sex education effects vary substantially across school districts from no effect in District 4 to a positive effect as large as half a standard deviation in District 3. The class size effect is near zero (or insignificant) and negative in all districts but District 7. The heterogeneous effects imply that endogenous sorting of individuals across districts may play an important role. To understand the mechanism of sorting, we would need more information on individual characteristics from which we could infer how school characteristics interact with individual preference and productivity. The estimated APE of school inputs are shown in column (7). We use the number of CSAT takers in each district to construct the weighted average. Compared to Park, Behrman and Choi (2012) who used the same data but a different model specification, our APE estimates are qualitatively similar but quantitatively different – the effect of single-sex education is much larger.

Our findings suggest that it is important to take district heterogeneity due to sorting between districts and unobserved school characteristics into account when estimating the average effect of school inputs on test score.

### REFERENCES

---

13We define school level averages of $\mathbf{L}_{s,d,*}$ as $\mathbf{\bar{L}}_{s,d,*} = \sum_{t \in T} \mathbf{L}_{s,d,t} / T$, $\bar{Y}_{s,d,*}$ is defined in the same manner.

14Note that $K_{s,d} = \sum_{s \in S_d} K_{s,d} / N_S(d)$, where $N_S(d)$ is the number of schools in district $d$.
